THE POWER OF TESTS BASED ON THE LENGTH OF RUNS

1. Introduction

The paper is a continuation of the research concerning the following tests based on the length of runs (see [2]):

- a test based on the maximum length of runs on one of the median (S_A),
- a test based on a smaller among the maximum lengths of runs above and below the median (S_D),
- a test based on a bigger among the maximum lengths of runs above and below the median (S_G).

These tests could be applied in verification of hypotheses on independence of the sequence of observations, in determination of the trend in the time series, in verification of the hypothesis on the linearity of the econometric model with one or more independent variables.

The aim of this paper is to formulate some conclusions concerning the power of tests based on the length of runs which are applied in verification of the hypothesis on independence of subsequent elements in a sample.

We shall confine our consideration to the case of stationary Markov chain with two states which are traditionally denoted as A and B and the transition matrix

$$\begin{bmatrix} P_{AA} & P_{AB} \\ P_{BA} & P_{BB} \end{bmatrix} = \begin{bmatrix} 1-q_0 & q_0 \\ q_1 & 1-q_1 \end{bmatrix}.$$

*Dr., Lecturer at the Institute of Econometrics and Statistics, University of Łódź.

Let $P_{n,\psi}$ be a distribution of this chain for each $\psi \in \Theta = \{(q_0, q_1): 0 < q_0 < 1, 0 < q_1 < 1\}$ and let $\Omega_n = \{A, B\}^n$ be a set of all- n -element sequences formed from elements A and B. Thus, we shall consider the probability spaces

$$(1) \quad M_{n,\psi} = (\Omega_n, 2^{\Omega_n}, P_{n,\psi}) \text{ for } \psi \in \Theta.$$

The formulated conclusions are based on the numerically determined power of tests basing on the distribution of the length of runs for $n = 1, 2, \dots, 100$ and on several dozen pairs chosen from the set Θ . The combinatorial formulae of probability connected with runs distribution presented in the literature (cf. [3], [4]) are inconvenient for numerical calculations. It is more efficient to use recursive formulae especially in the case when the calculations are made for subsequent values of n .

2. Recursive Formulae for Univariate Runs Distributions

We shall assign to each sequence

$$\omega = (x_1, x_2, \dots, x_n) \in \Omega_n$$

the following numbers:

- $N_A(\omega)$ - number of elements A in sequence ω ,
- $L_A(\omega)$ - number of runs consisting of elements A,
- $L(\omega)$ - total number of runs.

Assume that sequences $\omega \in \Omega_n$ are the realizations of the stationary Markov chain with the transition matrix

$$\begin{bmatrix} P_{AA} & P_{BA} \\ P_{AB} & P_{BB} \end{bmatrix},$$

where $0 < P_{AB}, P_{BA} < 1$. Hence, the stationary probabilities are given by the formulae

$$(2) \quad P_A = P(X_j = A) = \frac{P_{AB}}{P_{AB} + P_{BA}}, \quad P_B = P(X_j = B) = \frac{P_{BA}}{P_{AB} + P_{BA}}$$

for $j = 1, 2, \dots, n$.

Under these assumptions the probability distribution on the set can be presented by the formula

$$(3) P(\omega) = \frac{1}{P_{AB} + P_{BA}} P_{AA}^{(N_A - L_A)} P_{AB}^{L_A} P_{BA}^{(L - L_A)} P_{BB}^{(n - N_A - L + L_A)},$$

where n denotes sample size, $N_A(\omega)$ - the number of A-type elements in the sample, $L(\omega)$ - total number of runs, $L_A(\omega)$ - number of runs consisting of A-type elements.

Equation (3) results immediately from the identity

$$(4) P(\omega) = P(X_1=x_1) P(X_2=x_2|X_1=x_1) \dots P(X_n=x_n|X_{n-1}=x_{n-1})$$

after taking into account equation (2).

Determine for given n the following random variables:

S_A - the maximum length of runs consisting of A-type elements,

S_B - the maximum length of runs consisting of B-type elements,

$$S_D = \min \{S_A, S_B\},$$

$$S_G = \max \{S_A, S_B\}.$$

Having this notation we can formulate the following theorems whose proofs, as of little interest, are omitted.

Theorem 1. The distribution of variable S_A determined on $M_{n, \nu}$ is expressed by the recursive formula

$$(5) P(S_A=s) = Q_0^A(n,s) + Q_1^A(n,s),$$

where

$$Q_0^A(n,s) = \sum_{v=1}^{n-s} Q_1^A(n-v,s) q_0(1-q_1)^{v-1},$$

$$Q_1^A(n,s) = \sum_{v=0}^{s-1} Q_0^A(n-s,v) q_1(1-q_0)^{s-1} + \sum_{w=1}^s Q_0^A(n-w,s) q_1(1-q_0)^{w-1}$$

under initial conditions

$$Q_0^A(0,0) = Q_1^A(0,0) = \frac{1}{q_0+q_1}.$$

In the same way the distribution of S_B statistic is obtained.

Theorem 2. The distribution of variable S_G determined on $M_{n,v}$ is expressed by the recursive formula

$$(6) \quad P(S_G = s) = Q_0^G(n, s) + Q_1^G(n, s),$$

where:

$$Q_h^G(n, s) = \sum_{v=0}^{s-1} Q_{1-h}^G(n-s, v) q_h (1-q_{1-h})^{s-1} + \\ + \sum_{w=1}^s Q_{1-h}^G(n-w, s) q_h (1-q_{1-h})^{w-1}$$

for $h = 0, 1$, at initial conditions

$$Q_0^G(0, 0) = Q_1^G(0, 0) = \frac{1}{q_0 + q_1}.$$

The distribution of variable S_D can be determined on the basis of the following relation

$$(7) \quad P(S_D < s) = P(S_A < s) + P(S_B < s) - P(S_G < s).$$

3. Power Evaluation

On the basis of the recursive formulae presented in § 2 the power of randomized tests was determined numerically for $n = 1, 2, \dots, 100$ and for some pairs (p, ρ) , where

$$(8) \quad p = p_A \frac{q_1}{q_0 + q_1}, \quad \rho = 1 - q_0 - q_1.$$

The procedure was as follows:

- if $S^A < s_\alpha^A - 1$, then $H_0 : \rho = 0$ is accepted,
- if $S^A > s_\alpha^A$, then H_0 is rejected in favour of $H_1 : \rho > 0$,
- if $S^A = s_\alpha^A - 1$, then H_0 is accepted with probability r_α^A .

Let for the determined n, p , significance level α and $\rho = 0$

$$(9) \quad F_A(s) = P(S_A \leq s), \quad s = 0, 1, \dots$$

The critical value of the test based on S_A statistic will be therefore

$$(10) \quad s_{\alpha}^A = \min \{ s : F_A(s) > 1 - \alpha \}.$$

To this value the randomizing probability corresponds

$$(11) \quad r_{\alpha}^A = \frac{F_A(s_{\alpha}^A) - (1 - \alpha)}{F(s_{\alpha}^A) - F_A(s_{\alpha}^A - 1)},$$

which was presented in [2].

In the same way randomized tests based on statistics S_B , S_D and S_G were determined.

The results of power calculation for the tests S_A , S_B , S_D (verifying the hypothesis $H_0 : \rho = 0$) for $\alpha = 0.05$, $p = 0.5, 0.7, 0.9$, and $\rho = 0.1, 0.3, 0.5, 0.7, 0.9$ and $n = 5, 10, \dots, 100$, as well as for a simple alternative hypothesis $H_1 : \rho = \rho_1$ presented in Tables 1-4, allow to formulate the following conclusions.

1. The power of tests being considered is the highest for $p = 0.5$. (This is confirmed by already quoted result obtained by *B a t e m a n* [1]).

2. The test based on S_A statistic proved to be stronger than the test based on S_B statistic for $p > 0.5$, excluding the cases of very strong correlation ($\rho > 0.7$).

3. Among the tests of the runs length the most frequently used test S_G proved to be stronger than tests S_A and S_B , excluding the cases of big asymmetry ($\rho > 0.6$) and of very strong autocorrelation ($\rho > 0.7$).

4. The test S_G is stronger than the test S_D only for p close to 0.5 and for not very strong autocorrelation at a relatively small size of samples.

5. With the increase of p the difference between the power of tests S_A and S_G , and S_B and S_D decreases rapidly (excluding the cases of very small n ($n < 15$)). These differences remain significant only in the case of strong autocorrelation ($\rho > 0.5$).

Table 1

Power of tests of runs S_A
for some pairs (p, ρ) and $\alpha = 0.05$

| n | p = 0.5 | | | | | p = 0.7 | | | | | p = 0.9 | | | | |

MOC TESTÓW OPARTYCH NA DŁUGOŚCI SERII

Artykuł dotyczy analizy mocy testów opartych na maksymalnej długości serii z jednej strony mediany (S_A), mniejszej z maksymalnych długości serii z każdej strony mediany (S_D), większej z maksymalnych długości serii z każdej strony mediany (S_G) weryfikujących hipotezę o niezależności kolejnych elementów w próbie. W świetle przeprowadzonych badań uzyskano między innymi następujące wnioski: test S_G okazał się mocniejszy od testów S_A i S_D , wyjąwszy przypadki dużej asymetrii i autokorelacji; test S_G jest mocniejszy od testu S_D tylko w przypadku p bliskich 0,5 i małej autokorelacji; moc rozważanych testów jest największa dla $p = 0,5$.
